Abstract

Background: The prevalence depends on the socio demographic conditions, food intake patterns, cultural beliefs and is quite heterogeneous across the country

Methods: This was cross-sectional study. A total of 100 girls were interviewed and were investigated for their Hemoglobin concentration. A predesigned and pretested schedule was used to collect the information about the participants.

Results: The association between SES and anemia was found statically significant. The association between mother education and anemia was also found statically significant but association between type of family and anemia was also found statically Insignificant.

Conclusion: Nutrition education along with nutritional supplementation and iron folic acid tablets should be provided to all girls.

Key Words: Adolescent Girls, Anaemia, Socio-Demographic Characteristics, Education

Introduction:

Adolescence age group bridging childhood and adult life, marks the transition in social role with increasing potential to shape the country’s economic prospects and bring about change within the community. Adolescents to include persons aged 10-19 years.¹

There are about 1.8 billion adolescents globally today and 90% of the adolescent population is reported to be living in developing nations.² Even though adolescent age group is considered as relatively healthy period, increasing number of studies are proving that it is a great misconception. The adolescents are at risk of many diseases and nutritional disorders especially anemia is a major adolescent morbidity.³

The prevalence of anemia is reported to be ranging between 30% to as high as 68.8% as reported by various community based studies across India.⁴ This burden is comparatively similar and in some cases higher than prevalence reported from other developing countries.⁵

The prevalence depends on the socio demographic conditions, food intake patterns, cultural beliefs and is quite heterogeneous across the country.⁶

In spite of the number of interventions undertaken to combat anemia, its prevalence continues to be high in the adolescent
population. In the light of the rapid sociodemographic transition in the country, many of the adolescents are living in urban areas. Even though there were many studies conducted in India on prevalence of anemia in adolescent age group, studies focusing on urban adolescent females are very few. Considering the fact that majority of the urban adolescents are enrolled for their education in the private sector, they are quite often left of the government run prevention and control programmes.

Material and methods:
This was cross-sectional study. All the adolescent girls studying in standards 9th - 12th class who were given consent to hemoglobin estimation were included in the study. The girls ≥20 years, and those suffering from any chronic disease were not included in the study. A total of 100 girls were interviewed and were investigated for their Hemoglobin concentration. A predesigned and pretested schedule was used to collect the information about the participants.

Haemoglobin was estimated by the cyanmethaemoglobin method. It is measured in terms of g/dl. Capillary blood was drawn by finger prick method. Cuvette tube was pre-filled manually with Cyanmethemoglobin reagent. It was incubated for 5 minutes and finally readings were noted. For every sample a blank tube was placed in the machine to avoid the error or check the accuracy.

Results:
The mean age of adolescent girls were 13.2±2.3 years and mean Hb level was 10.1±2.1 gm/dl.

Most of the girls i.e.97 (97%) belonged to the socioeconomic class II, III,IV. The association between SES and anemia was found stastically significant. The association between mother education and anemia was also found stastically significant but association between type of family and anemia was also found stastically Insignificant.

**Discussion**

The National Pilot Programme on Control of Micronutrient Malnutriton launched in 1995 by the Ministry of Health and Family Welfare (2000) reported point prevalence of anaemia in various age groups and found to be high in both sexes. In adolescents, the prevalence rate of mild and moderate anaemia was also very-very high i.e., 65.8 per cent in boys and 81.3 per cent in girls with severe anaemia of boys 3.8 per cent and girls 6.0 %.

In the present study, the overall prevalence of anaemia was 73.00 per cent in adolescent girls, which is higher than the prevalence (34.5%) reported by Rawat et al (2000) among adolescent girls in rural area of Meerut. But it is reported to be low as compared to 73.7 per cent reported by Misra et al and multicentric study in 3 regions of India (Mumbai, Gujarat and Delhi) which showed anaemia prevalence as 62-65 per cent, 57-65 per cent and 48-50 per cent respectively in adolescent girls.

Reverse association was seen between socio-economic status and prevalence of anaemia in adolescent girls; lower the socio-economic status, and higher the prevalence of anaemia in our study. Thavraj and Reddy (1985) noted iron deficiency among 20 per cent of healthy non-anaemic high income group children. Hence it is evident that a significant proportion of the apparently healthy children belonging to the higher socio-economic class suffer from overt anaemia and may have latent iron deficiency anaemia if not anaemic. The possible reason for this could be the poor bio-availability of iron in Indian diet. Kapoor and Aneja (1991) noted prevalence of anaemia in 47 per cent of adolescent girls belonging to high socioeconomic group and 56 per cent in lower middle class. In a study by Vasanthi et al (1994), it was found that mean Hb showed a rising trend with improved socioeconomic status and most of the children belonging to lower socio-economic status were anaemic. This may be because of better availability of high quality of food for children with better socio-economic status.

The association between mother education and anemia was also found stastically significant in our study. Rawat et al also reported that the prevalence of anaemia was more in adolescent girls who are illiterate (42.2%) and just literate (40.3%) mothers as compared to educated mothers. It shows a significant correlation between the level of parental education and girl’s education. Particularly, the education of mothers is a significant factor for girl’s education.

**Conclusion**

Nutrition education along with nutritional supplementation and iron folic acid tablets should be provided to all girls.
