Abstract
Introduction: Present study was undertaken to compare the efficacy of intrathecal clonidine or buprenorphine with bupivacaine in lower abdominal surgeries.

Methods: 90 ASA I and II patients undergoing lower abdominal surgeries were randomly allocated into three groups (n=30). Group A received 3ml of 0.5% hyperbaric bupivacaine with 1ml normal saline, Group B received 3ml of 0.5% hyperbaric bupivacaine with 60mcg buprenorphine (1:5 dilution) and Group C received 3ml of 0.5% hyperbaric bupivacaine with 30mcg clonidine (1:5 dilution) respectively (Total volume 4ml). Onset time and duration of sensory and motor block, duration of analgesia, hemodynamics, VAS score, sedation score and side effect were compared.

Results: The duration of analgesia was significantly longest in Group C (354.50±38.48min), followed by Group B (277.10±25.47min) and Group A (131.50±20.15min) (p<0.001)

Conclusion: On comparing the two drugs, Clonidine appears to be superior in terms of postoperative analgesia.

Keywords: Clonidine, Buprenorphine, Intrathecal

Introduction

Pain as defined by the International Association for the study of Pain (ISAP) is an “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage”.¹ Lower abdominal surgeries may be performed under regional (spinal or epidural) or general anaesthesia. Spinal block is still the first choice because of its rapid onset, superior blockade, lower risk of infection, lesser failure rates, and cost-effectiveness but has the drawbacks of shorter duration of block and less postoperative analgesia. Local Anaesthetics when used alone is associated with short duration of action. Thus, early analgesic intervention is needed in postoperatively period. Various adjuvants have been used intrathecally to improve the quality and duration of spinal anaesthesia with better postoperative analgesia like epinephrine, neostigmine, midazolam, ketamine, fentanyl, buprenorphine, clonidine and dexmedetomidine.² With this background, this study was designed to compare the efficacy of intrathecal buprenorphine and clonidine with control group for onset and duration of sensory and motor block, duration of analgesia, sedation and to evaluate the side effects, if any.

Material and Methods

This was a randomized, double blind study, 90 ASA I and II, aged 25-55yrs, of either sex, body weight 45-70kgs scheduled for lower abdominal surgeries under spinal anaesthesia were chosen for the study.

Preanaesthetic check-up was done one day prior to the surgery. Patients were evaluated for any systemic diseases and laboratory investigations recorded. The patients with contraindication to spinal anaesthesia (e.g. coagulation defects, infection at puncture site and allergy to drugs used) were excluded from the study.

The patients were educated about the use of visual analog scale (VAS) scoring system. On the day of surgery patients were randomly allocated into three groups (n=30) using sealed envelope technique.

After confirming overnight fasting, patient was taken on the operation table, was connected to monitors and baseline vitals like BP, pulse rate, respiratory rate was recorded. An 18G intravenous cannula was inserted at the forearm level, lactated Ringer’s solution was administered as a bolus of 10ml/kg before subarachnoid block to all patients.

Vitals were noted just before lumbar puncture. Spinal anaesthesia was performed at L3-L4 interspace with the patient in sitting position by using a 25G Quincke needle under strict aseptic conditions. Free flow of cerebrospinal fluid was verified before injection of the anaesthetic solution 4ml volume, which was administered over 30 seconds. The drug compositions were according to group to which patients were allocated. Group A received 3ml of 0.5% hyperbaric bupivacaine with 1ml normal saline, Group B received 3ml of 0.5% hyperbaric bupivacaine with 1ml (60mcg) of buprenorphine (1:5 dilution) and Group C received 3ml of 0.5% hyperbaric bupivacaine with 1ml...
(30mcg) clonidine (1:5 dilution). The direction of the needle aperture was cranial during the injection. All patients were immediately placed in supine position. All the patients in three groups received identical volume (4ml) of study drug prepared in an identical syringe by an anaesthesiologist who was not involved in the anaesthetic management of the patients. Monitoring was done using continuous electrocardiography (lead II & V), heart rate, non-invasive blood pressure and continuous pulse oximetry (SpO₂) and patients were given 4.0L/min of oxygen by venti-mask. Vitals were checked every 5 minutes for first 30 minutes then every 10 minutes till the end of the surgery. When adequate spinal block was achieved, the time from the end of intrathecal injection to readiness for surgery was recorded. Then the patient was positioned for planned surgery.

Sensory blockade was assessed every 2 minutes by pinprick test bilaterally in the midclavicular line by using 25G needle. The onset of sensory block defined as the time from the intrathecal injection of the study drug to the time taken to achieve T5-T6 level of sensory block. The highest level of the block and the time to achieve the same was noted. Regression of sensory block was defined as the time taken for the sensory block to regress up to two segments of dermatome from the highest level achieved. Motor blockade was assessed using Modified Bromage Scale. The onset of motor block was defined as the time taken to achieve complete motor block (Bromage Score-3). Duration of motor block was assessed by recording the time elapsed from the maximum to the lowest Bromage score (3-0).

Hypotension was defined as a fall of MAP by more than 30% from baseline or a fall in SBP below 90mmHg and it was treated with incremental doses of mephentermine 6mg IV and IV fluids. Bradycardia, defined as heart rate below 55bpm, was treated with injection atropine 0.3-0.6mg IV.

Postoperatively, the pain was assessed by using visual analog scale (VAS) between 0 and 10 (0- no pain, 10- most severe pain). It was assessed every 30 minutes. Patients were allowed to receive rescue analgesics on VAS score of 3. Intravenous Diclofenac 75mg was given as rescue analgesic. This time from intrathecal injection to first administration of rescue analgesic (total duration of analgesia) was noted. This was the end point of our study. Postoperative sedation level was measured by using FOUR POINT SEDATION SCALE. The incidence of adverse effects such as nausea, vomiting, shivering, respiratory depression, sedation and hypotension were observed for 24 hours and managed.

**Statistical Analysis**

Statistical analysis was performed with SSPS (Statistical Package for the Social Sciences) software version 21 (SPSS inc., Chicago, IL,USA).

**Results**

The demographic data, such as age, sex, height, weight, ASA status, type of surgery and duration of surgery were comparable among the groups thereby not having any influence upon the outcomes. There was no statistically significant differences in the demographic variables between the groups (p>0.05).

All groups were comparable.

The hemodynamic parameters such as pulse rate, mean systolic blood pressure (SBP), mean diastolic blood pressure (DBP) and mean arterial pressure (MAP) were not statistically significant at different time intervals intraoperatively and postoperatively (p>0.05).

VAS score was statistically significant throughout the postoperative period and it was highest in Group A (control group) and lowest in Group C (clonidine group) (p<0.05) from 90 minutes postoperatively up to first request for rescue analgesic. (Figure 2)

Postoperative Sedation score was significantly more in patients of Group C and Group B as compared to control group (Figure 3). On comparing the three groups with regards to the adverse effects such as nausea, vomiting, hypotension, bradycardia, shivering and respiratory depression, the difference was found to be statistically insignificant (p>0.05) intraoperatively as well as early postoperatively. Discussion

Effective postoperative pain control is an essential component of the care of the surgical patient. Inadequate pain control, apart from being inhuman, may result in increased morbidity or mortality.9,10 Evidence suggests that surgery suppresses the immune system and that this suppression is proportionate to the invasiveness of the surgery. Good analgesia can reduce this deleterious effect.11,12

Regional analgesia have shown to improve surgical outcomes by decreasing intraoperative blood loss, postoperative catabolism, the incidence of thromboembolic events and by improving vascular graft blood flow and postoperative pulmonary function.13 Spinal anaesthesia is a commonly used regional anaesthesia technique for lower limb and lower abdominal surgeries owing to its well-known advantages like quick onset, excellent sensory and motor block and avoidance of complications of general anaesthesia.9 Various studies in the past have established the role of clonidine and buprenorphine as an adjuvant to local anaesthetic.

The antinociceptive properties of clonidine indicate that it might be useful as an alternative to intrathecal opioids for postoperative analgesia.14 The growing interest in alpha 2 agonist for intrathecal use has motivated innumerable research due to its ability to improve anaesthesia and neuraxial analgesia without the side effects of opioids such as respiratory depression, pruritis and urinary retention.

With this background a comparative study was performed to know the effectiveness of intrathecal buprenorphine versus clonidine as adjuvants to 0.5% hyperbaric bupivacaine in patients undergoing lower abdominal surgeries in relation to time of onset and duration of motor and sensory block and duration of analgesia. Incidence of side effects were also noted and compared. Our study showed that patients receiving 0.5% Bupivacaine had least duration of analgesia (131.50 minutes) whereas addition of 60 μg buprenorphine to 0.5% bupivacaine, the duration increased to 277.10 minutes but when 30 μg clonidine was
Kumar et al. | International Journal of Medical and Biomedical Studies (IJMBS)

used as an adjuvant, the duration was maximally prolonged up to 354.50 minutes. Our results have been strengthened by findings of Rashmi Pal et al 5 who demonstrated prolonged analgesia with 50 mcg clonidine (355.80±63.85 min) as compared to 75 mcg buprenorphine (283.20±51.84 min). Similarly, Srinivasagam K et al 7 also found addition of 50 mcg clonidine to hyperbaric bupivacaine increases the duration to first time of rescue analgesia. Similar results were shown by Lomate P et al 6 who used 30 mcg clonidine. We also used 30 mcg clonidine in our study which showed similar results to all above studies.

Our results were further strengthened by findings of Negi AS et al 5 who showed duration of analgesia was more with 37.5 mcg clonidine (355.80±63.85 min) as compared to 75 mcg buprenorphine (283.20±51.84 min). The onset of sensory and motor block was not prolonged in clonidine and buprenorphine. Our results were supported by the study done by Lomate P et al 6, Rashmi Pal et al 5 and Srinivasagam K et al 7. The duration of sensory block and motor block was more with clonidine as compared to buprenorphine and control group. Lomate P et al 6 observed similar results which used 30 mcg clonidine in their study.

In our study hemodynamic parameters were comparable at different time intervals intraoperatively and postoperatively. Many studies who have used very low doses of intrathecal clonidine such as 15-30 mcg in humans found no hemodynamic instability which is proven in our study as we have used low dose clonidine (30 mcg). Our findings are similar to study done by Negi AS et al 5 who had used 37.5 mcg clonidine in patients undergoing lower limb surgeries showed no hemodynamic instability.

In our study, postoperative sedation score was highest with clonidine group. Patients developed sedation as assessed by sedation scores but were easily arousable.

On comparing the three groups with regards to adverse effects like hypotension, bradycardia, nausea, vomiting, respiratory depression and shivering the difference was statistically insignificant. Srinivasagam K et al 7 reported increased incidence of hypotension and bradycardia with 50 mcg of clonidine. This difference could be due to the use of lower doses (30 mcg) in our study. One limitation of our study was that a therapeutic end point of VAS score 3 or request for analgesic was used. 24 hours total analgesic requirements were not recorded which would have better demonstrated the analgesic qualities of the studied drugs. However, our study found buprenorphine and clonidine both prolonged analgesia and decreased postoperative VAS scores.

Conclusion
Both buprenorphine (60 mcg) and clonidine (30 mcg) were effective and safe as adjuvants to 0.5% hyperbaric bupivacaine when given intrathecally in patients undergoing lower abdominal surgeries. Clonidine appeared to be better in terms of prolongation of the duration of analgesia as compared to buprenorphine. Clonidine provide adequate sedation in postoperative period without significant postoperative complications.
